Chemical modification of nanocrystal surfaces is fundamentally important to their assembly, their implementation in biology and medicine, and greatly impacts their electrical and optical properties. However, it remains a major challenge owing to a lack of analytical tools to directly determine nanoparticle surface structure. Early nuced magnetic resonance (NMR) and X-ray photoelectron spectroscopy (XPS) studies of CdSe nanocrystals prepared in tri-n-octylphosphine oxide (1) and tri-n-octylphosphine (2), suggested these coordinating solvents are datively bound to the particle surface. However, assigning the broad NMR resonances of surface-bound ligands is complicated by significant concentrations of phosphorus-containing impurities in commercial sources of 1, and XPS provides only limited information about the nature of the phosphorus-containing molecules in the sample.

More recent reports have shown the surface ligands of CdSe nanocrystals prepared in technical grade 1, and in the presence of alkylphosphonic acids, include phosphonic and phosphinic acids. These studies do not, however, distinguish whether these ligands are bound datively, as neutral, L-type ligands, or by X-type interaction of an anionic phosphonate/phosphinate moiety with a surface Cd\(^{2+}\) ion. Answering this question would help clarify why ligand exchange with such particles does not proceed generally as expected based on the accepted L-type ligand model. By using reagents with reactive silicon-chalcogen and silicon-chlorine bonds to cleave the ligands from the nanocrystal surface, we show that our CdSe and CdSe/ZnS core–shell nanocrystal surfaces are likely terminated by X-type binding of alkylphosphonate ligands to a layer of Cd\(^{2+}\)/Zn\(^{2+}\) ions, rather than by dative interactions. Further, we provide spectroscopic evidence that 1 and 2 are not coordinated to our purified nanocrystals.

We synthesized 3–6 nm CdSe nanocrystals by reacting tri-n-octylphosphine selenide with anhydrous cadmium-n-octadecylphosphonic acid (3) in 1 at 315 °C. ZnS shells were grown on these cores by reacting zinc-n-octadecylphosphonate with bis(trimethylsilyl)sulfide under similar conditions. Both 1 and 3 were recrystallized prior to use and shown to be free of phosphorus-containing impurities with NMR spectroscopy. To ensure the purity of the nanocrystal product, removal of remaining cadmium- and zinc-n-octadecylphosphonate, insoluble coordination polymers, was accomplished by their depolymerization and dissolution with octylamine, followed by fractional precipitation of the nanocrystals (see Supporting Information).

\(^1\)H NMR spectra of purified nanocrystals in \(d_8\)-toluene showed broad resonances for methylene groups (\(\delta = 1.3–4.0\) ppm) and methyl groups (\(\delta = 0.9–1.0\) ppm) in a ratio of ~17:1 representative of octadecyl chains (Figure S1). Additionally, a broad resonance of low intensity is visible between \(\delta = 7.8–9.2\) ppm, which we tentatively assign to a low concentration of acidic hydrogens present in the ligand shell. A \(^1\)H\(^{31}\)P NMR spectrum of a concentrated sample (278 mg/mL) showed a broad bimodal resonance from \(\delta = 10–40\) ppm reminiscent of the spectrum published by Bawendi and co-workers, and originally interpreted to be characteristic of surface-bound 1 and 2 (Figure 1). Neither the \(^1\)H nor the \(^1\)H\(^{31}\)P NMR spectrum showed sharp resonances that might arise from “free” surfactant molecules.

Removal of these surface-bound ligands was accomplished by adding bis(trimethylsilyl)selenide (4) to a solution of the CdSe nanocrystals in \(d_8\)-toluene. Shortly after addition (10–60 min) the sample became turbid and the nanocrystals then slowly settled out of solution. NMR spectra of these solutions immediately after mixing are dramatically sharpened because of the release of the surface-bound ligands (Figure 1). In particular, three sharp resonances characteristic of “free” small molecules appeared in the \(^1\)H\(^{31}\)P NMR spectrum that we assign to \(O,O'\)-bis(trimethylsilyl)octadecylphosphonic acid (5) and the racemic and meso forms of \(O,O'\)-bis(trimethylsilyl)octadecylphosphonic acid anhydride (6) (Scheme 1). Similar reactivity was observed with bis(trimethylsilyl)sulfide. Both mass spectrometry and an independent synthesis of these reaction byproducts confirm our assignment (see Supporting Information).

The presence of the n-octadecylphosphonic acid anhydride in the ligand shell likely arises from reaction of 3 with trioctylphosphine selenide during the synthesis of CdSe, rather than as a byproduct of the ligand cleavage reaction. This is supported by the observation that increasing amounts of 6 relative to 5 are cleaved from nanocrystals synthesized in reactions run to higher conversion of the cadmium and selenium nanocrystal precursors.

The reactivity of the silicon–selenium and silicon–sulfur bonds and the stability of the newly formed silicon–oxygen bond...
trimethylsilyl bound chalcogenides

a mixture of toluene saturated with anhydrous tridecyltrimethylsilane to a toluene solution of nanocrystals, the alkylphosphonate ligands for chloride ligands. Adding anhydrous NaCl and diethylamine to a toluene solution of nanocrystals, the number of adsorbed chloride anions from the reaction byproducts in the presence of added nanocrystals, a thiolate is formed. Encouraged by our nanocrystal derivatization experiments with CdSe/ZnS core-shell particles, we sought to exchange to the CdSe nanocrystal sample resulted in minimal changes to the XPS of chloride-terminated CdSe nanocrystals (black) (Scheme 3). S9, 10 Analysis of the hexane-soluble portion with 1H NMR spectroscopy and ESI-TOF mass spectrometry showed the presence of 5−7 but no 31P NMR resonances for 1 and 2.

Encouraged by our nanocrystal derivatization experiments with trimethylsilyl bound chalcogenides 4 and 7, we sought to exchange the alkylphosphonate ligands for chloride ligands. Adding anhydrous chlorotrimethylsilane to a toluene solution of nanocrystals, results in rapid particle aggregation. Repeating this experiment in a mixture of toluene saturated with anhydrous tridecytrimethylammonium chloride (8), however, prevented nanocrystal aggregation. Removal of excess 8 by centrifugation and subsequent fractional precipitation with hexane gave nanocrystals that are soluble in toluene and chloroform. 31P NMR spectroscopy of the reaction byproducts in d8-toluene showed the presence of 5 and 6, while a 1H NMR spectrum of the nanocrystals showed resonances characteristic of the tridecytrimethylammonium ion (Scheme 3). Repeating this experiment with CdSe/ZnS core−shell particles resulted in a 25% decrease in the fluorescence quantum yield.12

XPS of the Cl-functionalized nanoparticles made soluble with 8 was performed to demonstrate the binding of chloride to the nanoparticle surface. Binding energies of Cl 2p electrons are sensitive to their coordination environment with reported values for tetraalkylammonium chloride salts of 196 eV, while CdCl2 shows Cl binding energies of 199 eV.13 XPS analysis of our chloride-terminated nanocrystals dropcast on a gold substrate showed Cl binding energies of 199 eV with little contribution below 198 eV, ruling out the presence of significant amounts of “free” 8 (Figure 2).

The facile ligand cleavage and exchange reactivity of the trimethylsilylchalcogenides and chlorotrimethylsilane presented above suggests that our nanocrystal surfaces may be terminated by X-type binding of anionic alkylphosphonate moieties to Cd2+ ions on the crystal surface. This hypothesis is best supported by a model where a layer of excess cadmium ions bind to the Lewis basic selenide surface sites of the CdSe core and are charge balanced by the phosphonate ligand. Previously reported Rutherford backscattering experiments support the conclusion that CdSe nanocrystals contain excess Cd ions on their surfaces. This, however, does not strictly follow from our ligand cleavage experiments, since a control experiment showed free phosphonic acid (3) and its anhydride also produce 5 and 6, respectively, on reaction with 4.

To further investigate the nature of the binding between 3 and the nanocrystal surface, we studied the direct reaction of our CdSe nanocrystals with thiols. Addition of 2-methoxyethanethiol (9) or its long chain counterpart 2,5,8,11-tetraoxatridecane-13-thiol (10) to the CdSe nanocrystal sample resulted in minimal changes to the resonances for the surface-bound octadecl chains in the 1H NMR, though a broad resonance (δ = 3.2−4.5 ppm) appeared upfield of the free thiol.15 Repeated precipitation from toluene by addition of hexane furnished nanocrystals that retain the broad signature of the bound thiol (δ = 3.2−4.5 ppm) as well as the starting octadeclphosphonate ligands in an approximate 1:1 ratio (Supporting Information, Figure S10). No sharp lines indicative of “free” surfactant molecules were visible. Additionally, the nanocrystal fluorescence was immediately quenched upon addition of 9 and 10. Both observations indicating that the thiol binds the nanocrystal surface. Repeating this experiment in the presence of added triethylamine, however, resulted in rapid (t < 10 min) sharpening of the aliphatic resonances in the 1H NMR spectrum. At the same time two sharp resonances in the 31P NMR spectrum (δ = 16.6, 26.1 ppm) appeared that we assign to the conjugate base of octadeclphosphonic acid and octadeclphosphonic acid anhydride.16

This indicates 10 will only displace the alkylphosphonate ligands upon deprotonation by triethylamine suggesting that anionic alkylphosphonate moieties are bound to excess cationic cadmium sites, rather than by a simple dative interaction. Accordingly, the incoming thiol must convert the alkylphosphonate ligand to an equivalent of phosphonic acid in order to displace it from the nanocrystal and form a Cd2+-thiolate interaction. The lack of this reactivity in the
absence of added base, likely arises from the greater pKₐ of thiols, which remain preferentially protonated over the alkylphosphonate oxygen. By adding triethylamine, however, the bound thiol can be deprotonated by the external base driving formation of a surface Cd-thiolate and displacement of a triethylammonium octadecylphosphonate salt.

In addition to X-type octadecylphosphonate binding, adsorption of thiols to our nanocrystal surfaces, without displacing the octadecylphosphonate ligands, suggests nanocrystal surfaces also contain L-type coordination sites. This helps explain why our chloride-terminated nanocrystals are soluble in the presence of tetraalkylammonium chloride salts, and the numerous reports that amines, phosphines, and thiols can change nanocrystal growth kinetics, solubility, and optical properties.¹⁷

This picture of a CdSe nanocrystal surface is particularly interesting in light of recent single crystal X-ray structures of monolayer-protected Au clusters.¹⁸ Those results complement our understanding in light of recent single crystal X-ray structures of amines, phosphines, and thiols can change nanocrystal growth kinetics, solubility, and optical properties.¹⁷

The properties of these nanocrystals. Studies of these effects are underway in our laboratory.
